Option Writing: Using VIX to Improve Returns

August 2, 2018

Abstract

Buy-Write and Put-Write strategies have been shown to match market returns with lower volatility resulting in higher risk-adjusted performance. The strategies benefit from the fact that implied volatility of options is generally higher than actual realized volatility. In this paper we show that this premium is higher at elevated levels of implied volatility (as represented by the VIX index level). Based on this finding we propose a simple conditional strategy in which one sells options at elevated levels of the VIX. Using data from 1990 through 2018, we find that this conditional strategy outperforms both the market and continuous option selling strategies on an absolute and risk-adjusted basis.

Keywords: Option Writing, VIX, volatility, Buy-Write

JEL Codes: G11, G12, G19

The writing of put and call options has frequently been used as an adjunct to porfolio management. Selling options to buyers, who use them either for protection or to leverage a portfolio's return, has been analogized to the provision of casualty insurance. Just as the insurance companies that write home insurance benefit from selling fire insurance, so do the writers of options. They capture volatility risk premium, which reflects the compensation investors earn for providing insurance against market losses. Option prices reflect this volatility premium because of market participants' tendency to overestimate the probability of significant losses[1] and an investor can capture this premium by selling options.

There are generally two option 'writing' or selling strategies: the first is a "buy-write." It entails writing call options against a long position in a stock or a market index. The other is "put writing", where the manager sells put options, while holding a porfolio of U.S. Treasury Bills to ensure that the writer can fulfill his contract obligation should the put buyer exercise the option. In both option selling strategies, the upside potential is capped even when the underlying asset price rises considerably higher than the strike price; however, when the underlying asset price falls, option writing cushions the losses to the extent of the cash received through the sale of options. As a result, the returns of option selling strategies tend to have lower volatility than that of the underlying asset.

Several prior studies have documented the attractive returns, especially risk-adjusted returns, of option writing strategies. We contribute to the literature by demonstrating that an

---

[1] Investor behavioral bias to overestimate downside risk has been documented by various studies. For example, Goetzmann et al. (2016) discuss survey results which show that nearly two-third of retail as well as institutional investors consistently believe that there is a 10% chance of a catastrophic market crash within the next six months, when in reality the historical likelihood of such an event is about 1%. See also Ang, Israelov et al. (2018).

3

investor can considerably improve her returns by deploying these strategies only during periods when anticipated volatility (as measured by VIX) is higher than usual. The economic intuition for our result stems from the observed differences in volatility risk premium in different market environments. We show that the difference between implied volatility and realized volatility varies across VIX regimes. Implied volatility is based on the market's forecasts of future volatilities extracted from the prices of options written on the asset of interest. The difference between the implied and realized volatility is particularly pronounced when the VIX index, which reflects the market's implied volatility, is elevated. Thus, a strategy of selling options during high VIX regimes is expected to yield superior returns.

We find that a 'conditional' option writing strategy of staying fully invested in the market when the VIX is relatively low and writing calls or puts when VIX is high produces higher returns and lower volatility and downside risk (resulting in higher Sharpe and Sortino ratios) than the market during the period 1995 through June 2018. This conditional option writing strategy also performs better—both in absolute and risk-adjusted basis—than the returns of unconditional option writing.

In the next section we review the relevant literature. In the third section, we examine the time-varying characteristics of volatility risk premium by analyzing the relationship between implied and realized volatility in different market environments. The findings in this section provide the motivation for exploring the risk and return characteristics of alternative option writing strategies, including conditional optional writing; we undertake this examination in the fourth section of the paper. The final sections contain areas for further research and concluding comments.

4

RELEVANT PRIOR LITERATURE

The literature relevant to our study can be segregated into two broad groups: one that pertains to measuring and forecasting volatility and another that deals with option selling strategies. While we begin our review with the first strand of the literature, we will focus mainly on the second, as it is more directly relevant to our paper.

There is a very rich body of studies on modeling volatility. Their roots lie in Engle's (1982) path breaking ARCH paper, which set out a model of forecasting volatility as a time-varying function of current information. Since then the GARCH class of models, initially created by Bollerslev (1986), and with many subsequent variations, have been extensively used in volatility modeling. One aspect of this extensive body of literature particularly relevant for our study is the observation that the volatility of equity index returns respond asymmetrically to past negative and positive return shocks, *with negative returns resulting in larger future volatilities*. As a possible explanation for this asymmetry researchers have posited a "volatility feedback" effect, i.e., heightened volatility requires an increase in the future expected returns to compensate for the increased risk, in turn necessitating a drop in the current price to go along with the initial increase in the volatility.[2]

Turning to the second strand of literature, we note that while there are several studies on option writing, the vast majority of them have focused on buy-write rather than put-write

---

[2] See Andersen, Bollerslev et al. (2006) for an excellent discussion on this issue. The most commonly used GARCH formulations for describing this type of asymmetry are the variants of GARCH models of Glosten, Jagannathan and Runkle (1993) and Zakoïan (1994), the asymmetric GARCH model of Engle and Ng (1993), and the exponential GARCH model of Nelson (1991).

5

strategies. That is in large part explained by the similarities in return characteristics of the two option writing strategies.

In 2002, the Chicago Board Options Exchange (Cboe) introduced the Buy Write Index (BXM), which is designed to track the performance of a covered call strategy where the underlying is the S&P 500 index. One of the earliest studies on the performance of this buy-write strategy was by Whaley (2002), who showed that from 1988–2001 the index provided nearly the same return as the S&P 500 while having a standard deviation of returns one third lower than that of the S&P 500. Two subsequent studies, by Feldman and Roy (2004) and by Callan Associates (2006) found essentially the same results.

Ungar and Moran (2009) review the performance of writing put options compared with various other strategies over the period 1986-2008 and find that it outperforms a plain vanilla buy-writing strategy. To help explain this outcome, they point to previous studies such as Rubenstein (1994) and Jackwerth (2000) which establish that out of the money put options are systematically overpriced. Academics have provided several explanations for the mispricing of put options. For example, Bakshi and Kapadia (2003) consider overpricing in the context of negative volatility risk premium while Garleanu, Pedersen, and Poteshman (2006) connect it to excess demand for downside protection. In addition to plain vanilla covered call or put-write strategies, numerous studies have documented how variations in the options selected for selling have the potential to improve returns. McIntyre and Jackson (2007) undertook an empirical evaluation of covered call writing for a variety of maturity dates, strike prices, and assets; they found that call-writing strategies provide attractive returns, particularly on a risk-adjusted basis. Figelman (2008) synthesized a formula for the expected return of the covered-call strategy. He observed: "the

6

[covered call] strategy on the S&P500 Index has exhibited strong historical risk-adjusted performance relative to the stock index itself. In order for investors to find the …strategy attractive, they must be convinced that going forward, *implied volatility will be higher, on average, than the corresponding realized volatility*." (Figelman, 2008, 91-92) In fact, we demonstrate in our paper, that has indeed been the case for the last three decades.

He, Hsu, Rue (2014) examine various covered call strategies using different maturity dates and strike prices with the S&P500 index as the underlying asset. They show that the performance is maximized when writing at the money calls, with three months maturity dates. While most prior studies have examined strategies with a buy-write ratio of one, Diaz and Kwon (2017) explore the optimization of the covered call strategies by using different combination of calls; they find that from a risk-return perspective it is often optimal to sell a mix of options with different strike prices.

A study of similar vein is Hill et al. (2006), which explores covered calls where the strike prices are set according to the volatility of the underlying asset. They find superior performance of writing calls with less than a 30% probability of exercise or with a strike price at least 2% out-of-the-money. Che and Fung (2011) perform a similar analysis with Hang Seng Index futures as the underlying. They conclude that the performance of the strategies depends greatly on market conditions. While prior studies have focused on the optimal option writing strategies based on factors such as strike prices, expiration times and buy-write ratios, we contribute to the literature by examining the returns of a strategy that writes options only in selective market environments characterized by elevated VIX.

7

RELATIONSHIP BETWEEN VIX AND VOLATILITY

The VIX is the most popular index purporting to measure the market's expectation of the next month's volatility of the stock market. The rules-based index is derived from the prices of a wide variety of put and call options on the S&P 500 index (henceforth S&P). Because of its tendency to rise during periods of unsettled declining stock prices, the VIX is often called the "fear index". The Chicago Board Options Exchange has created an historical record of the index dating back to 1990. In this section, we examine the characteristics of the index and some of its statistical properties.

Under the current methodology the VIX is constructed using S&P option prices for options expiring between 23 and 37 days in the future (Cboe, 2018). As such the VIX is intended to represent the 30-calendar day (approximately 21-trading day) forward volatility of the S&P as a proxy for market volatility.

We introduce the following notation. Let V_t represent the index value of the VIX on day t. Let R_t equal a measure of realized volatility of the S&P index over (approximately) the past month. R_t is calculated as the standard deviation of the S&P returns for the past 21-trading days including the current day, denoted by $t=0$. The S&P returns are the log returns derived from the closing values of S&P 500 Total Return Index (henceforth SPTR). This is shown formulaically in equation (1).

$$\textbf{Realized Volatility} \text{ on day } t\text{: } R_t = Std(r_{t=0}...r_{t=-20}) \tag{1}$$

We define forward volatility (F_t) as the standard deviation of market return over the next 21 trading (starting with day t+1). This is shown formulaically in equation (2).

8

Forward Volatility on day t: $F_t = Std(r_{t=+1}...r_{t=+21})$ (2)

For ease of comparison to the VIX throughout this paper we show both realized and forward as daily volatility annualized and multiplied by 100.

In Exhibit 1 we examine how VIX has been related to past volatility and how well it predicts future volatility. Our analysis uses the daily closing values for the index for the nearly thirty-year period starting in January 1990 through June 2018. These three decades allow us to look at the relationship between the VIX and actual volatility in a variety of market conditions.

9

Exhibit 1: Regression Analysis of VIX and Volatility
January 1990 - June 2018

Panel A: Explained Variable - VIX

Explanatory Variable	Coefficient	T-stat
Realized Volatility	0.7596	161.13
Intercept	7.7634	92.83
Adjusted R-sq	0.7840	

Panel B: Explained Variable - Forward Volatility

Explanatory Variable	Coefficient	T-stat
Realized Volatility	0.7434	93.80
Intercept	3.8837	27.60
Adjusted R-sq	0.5522	

Panel C: Explained Variable - Forward Volatility

Explanatory Variable	Coefficient	T-stat
VIX	0.9133	106.55
Intercept	-2.4613	-13.76
Adjusted R-sq	0.6134	

In Exhibit 1, Panel A contains the result of regressing the VIX on realized volatility. We note that VIX is highly correlated with past (realized) volatility as demonstrated by an adjusted R-squared of 0.78. Panel B shows that there is also statistically significant persistence in volatility but that the R-squared between past and future volatility is only 0.55. Finally, Panel C shows that VIX does a better job than past volatility alone in explaining future volatility (R-squared of 0.61), but the relationship leaves nearly 40 percent of forward volatility unexplained. That said, it is worth

noting that VIX, which is based upon option prices, does provide at least some additional information concerning the future path of volatility when compared with realized volatility alone.

As previously discussed, it is well known that VIX tends to overstate both realized and forward volatility. Exhibit 2 summarizes this relationship between VIX and the two measures of volatility using data from January 1990 through June 2018. In Panel A we show the difference between VIX and both realized volatility and forward volatility by VIX quartile. Consistent with prior research, we find VIX levels are higher than both realized past volatility as well as the forward volatility over the next 21 trading days with an average overestimation of approximately 4 points.

Exhibit 2: VIX and Volatility
January 1990 - June 2018

Panel A			Difference Between VIX and:	
VIX Quartile	**Intra-Quartile Range**	**Mid-point of VIX Quartile**	**Realized Volatility**	**Forward Volatility**
1	9.14 - 13.65	11.40	3.48	2.88
2	13.66 - 17.44	15.54	4.00	3.90
3	17.45 - 22.73	20.09	4.71	4.50
4	22.74 - 80.86	51.80	4.26	5.27
Overall			**4.11**	**4.14**

Panel B	Deviation From Average Difference:			
VIX Quartile	**Realized Volatility**		**Forward Volatility**	
1	-0.63	**	-1.26	**
2	-0.11		-0.23	*
3	0.60	**	0.36	*
4	0.15		1.13	**

Note:
* denotes the difference is statistically significant at the 95% level
** denotes the difference is statistically significant at the 99% level

11

As discussed earlier, this systematic overstatement is commonly attributed to the buy-sell dynamics of the underlying options upon which VIX is based. Because VIX has a negative correlation with stock prices, equity investors find the purchase of volatility-sensitive derivatives offers important insurance benefits. Investors who are long VIX realize gains when the market falls thereby offsetting negative equity returns. Such buying of volatility derivatives increases their prices and leads to a systematically larger prediction of future volatility than is actually realized.

What is particularly interesting is that the difference between VIX and observed volatility are larger at higher levels of volatility. For example, as shown in the last column of Panel A, in the lowest quartile of VIX values, VIX overstates forward volatility by 2.88 points; while in the highest quartile by 5.27 points.

Exhibit 2, Panel B further examines the deviations by quartile. In Panel B, we look at the average deviation in each quartile compared with the overall average deviation. The last column contains these values for the comparison between VIX and forward volatility. The values show a clear pattern – VIX understates forward volatility in the lower quartiles and overstates in the upper quartiles. These differences between VIX and forward volatility in each of these quartiles are statistically significant a noted in the exhibit. These findings provide the motivation for the strategies discussed in the next section.

PERFORMANCE OF CONDITIONAL STRATEGIES

Because it has been generally perceived that expected volatility – which is the most important determinant of option prices – tends to overstate realized volatility, it has been argued that

12

strategies involving option writing may produce better risk-reward outcomes than simple long-only equity strategies. Some investors buy put options to protect the money value of their portfolios from capital losses in the event of a market decline. These are called protective puts. But investors may be overpaying for that protection if the implicit volatility in the prices of put options is systematically higher than realized volatility.

Option writing is then recommended as an optional strategy to take advantage of the possibility that people overpay for protection. Insurance companies that write fire-insurance policies profit from setting rates that are far higher than would be required on the basis of the actual probability that the insured houses would burn down. By analogy, the argument is that the writers (i.e. sellers) of put options will find that providers of volatility insurance would profit under most market corrections.

Option Writing Strategies

There are two kinds of writing strategies that are commonly employed. The first is to go long an individual stock, or an ETF representing a market index, while simultaneously selling (writing) call options on the security or index. The sale is often made "at the money," i.e., at the same price at which the security or ETF is trading. Writing puts typically involves selling put options "at the money" while depositing margin in the form of safe U.S. Treasury bills with a maturity equal to the duration of the option.

Exhibit 3 represents the payoffs from both strategies. The graph assumes that the index (or stock) sells at $40 and that the call and put options sell at $4 per share. The solid line represents the payoffs from buying the index or stock if the price rises or falls. The buyer of 100 shares benefits

13

or loses in exact proportion to his investment as the price rises or falls. The investor who is long

on the index and writes a $4 call gains 10 percent at any price above $40. While the call buyer

exercises the call at any price above $40, the investor receives both the sale proceeds and the $4

option premium. If the price falls below $40, the option is not exercised and the investor is left

holding a depressed stock. Her loss is reduced by the receipt of the option premium and she suffers

a net loss only if the price goes below 36. The dotted line illustrates the payoff. The writer of the

100 puts is in exactly the same position. Neither calculations take into account any dividends from

the long holding or interest on the margin deposited by the put seller.

Exhibit 3: Illustration of Payoffs

Illustration of Payoffs
Buy Write and Sell Put Index at 40
Put and Call (at the Money) at 4
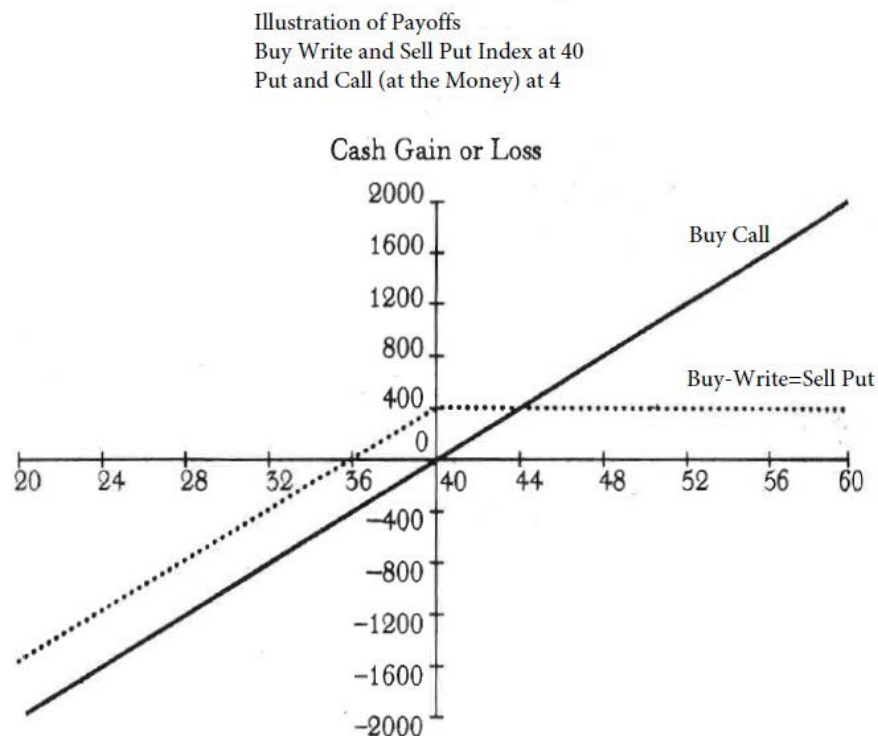

As noted earlier in the paper, several studies have documented the advantages of these strategies which broadly result in similar returns to the overall market with lower volatility which translates into higher risk-adjusted return than the market. There are a few key features that make this possible: (a) when the underlying falls, the losses are partially offset by the premium received; (b) the treasuries (in case of put-write) provide yield or the underlying securities (in case of buy-write) provide dividends thereby augmenting returns; and (c) the capped upside reduces volatility of returns.

Data on Option Writing Strategies

The Cboe provides indices which represent the historic returns of both buy-write (BXM) and put-write (PUT) strategies. The Cboe provides historical data for these two indices using a consistent methodology going back to June 1986.

Both the BXM and PUT indices utilize a monthly roll. In the case of the BXM, this means that the index is constructed as if the investor held the S&P and each month on the date of expiration of the prior monthly option contract the investor sells the relevant option at a weighted average price. Dividends paid on the component stocks underlying the S&P and the dollar value of option premium deemed received from the sold call options are functionally "re-invested" in the covered S&P portfolio. The PUT index follows a similar monthly roll process but holding risk-free assets instead of the S&P. Given this monthly roll feature of the BXM and PUT indices, in this section we utilize monthly performance data to evaluate these strategies.[3]

---

[3] Detailed writeup of methodology can be found here: https://www.cboe.com/micro/BXM/BXMDescription-Methodology.pdf and http://www.cboe.com/micro/put/putwritemethodology.pdf

15

Exhibit 4: Performance Statistics of Different Strategies
January 1990 - June 2018

	SPTR	Buy-Write	Put-Write
Average Return	9.29%	8.20%	9.28%
St. Deviation	14.25%	10.13%	9.79%
Sharpe	0.46	0.54	0.67
Sortino	0.67	0.75	0.90

Exhibit 4 shows summary performance statistics for the S&P 500 Total Return index (SPTR) as well as the BXM and PUT indices from January 1990 through June 2018. The results are broadly consistent with prior studies. Over this time period all three have similar returns, with the BXM and PUT indices experiencing lower volatility and therefore higher risk adjusted returns than S&P as demonstrated in higher Sharpe and Sortino ratios.[4]

Conditional Strategy Construction

As discussed earlier, we observe that the difference between VIX (as a measure of implied volatility) and future volatility increases at higher levels of VIX. We therefore expect the returns of the BXM and PUT indices, which reflect the gains from selling options, to be higher at higher levels of the VIX. Exhibit 5 shows the excess performance of the BXM and PUT indices over the SPTR by VIX quartiles.

---

[4] As discussed earlier the BXM and PUT represent a similar theoretical payoff, despite this theoretical consistency, the rationale for the excess returns earned by PUT over BXM are discussed here: http://www.cboe.com/micro/bxm/bxm-put-conundrum.pdf.

Exhibit 5: Excess Return by VIX Quartile
January 1995 - June 2018

VIX Quartile	Excess Return Over SPTR	
	Buy-Write	Put-Write
1	-4.1%	-4.3%
2	-6.4%	-4.8%
3	0.4%	3.3%
4	1.6%	2.4%

The VIX quartiles are constructed such that they are free from hindsight bias. In particular, we determined the quartile cutoffs for the VIX based only on historical data i.e., based VIX levels in the period prior to the current month. Therefore, as one moves forward in time, the strategies add one month of additional data to determine the VIX cutoff. To make sure there is a sufficient sample on which to base these cutoffs we start in 1995, which provides us with a minimum of five years of prior history. We then use the median VIX level of the *prior* month to categorize the excess returns of BXM and PUT indices into VIX quartiles.

The results are consistent with our findings in Panel B of Exhibit 2. The two option selling strategies provide positive excess returns in both the third and fourth VIX quartiles and underperform the market in the first two quartiles.

We utilize these results to construct two conditional option-writing strategies that seek to capitalize on this pattern. The conditional strategies are based upon a simple rule: invest in S&P if VIX is below its historical median and engage in an option writing if VIX is above the historical median.

For example, starting in January 1995, we determine the median historical VIX level, using data for the period January 1990 through December 1994. At the beginning of January of 1995, if the

17

median VIX level in the prior month (i.e., December 1994) is higher than the historical median VIX value (i.e., using data between 1990 and 1994) than we enter the option selling strategy. If the median VIX is lower than the median value, we stay in the S&P. We make this same evaluation in each subsequent month by looking at the full VIX history to up through the prior month to compute the historical VIX median and compare the median VIX level of the prior month to the historical median.[5] By using only historical data in deciding whether or not to engage in option selling, we avoid any hindsight bias.

Conditional Strategy Performance

Exhibit 6 compares the performance of these conditional strategies to the original strategies and the market. The conditional strategies are shown in the final two columns.

Exhibit 6: Performance Statistics of Different Strategies
January 1995 - June 2018

	SPTR	Unconditional Buy-Write	Unconditional Put-Write	Conditional Buy-Write	Conditional Put-Write
Average Return	9.49%	7.64%	8.67%	10.09%	10.88%
St. Deviation	14.63%	10.59%	10.40%	11.58%	11.36%
Sharpe	0.49	0.50	0.61	0.67	0.75
Sortino	0.71	0.69	0.81	0.95	1.05

The results are clear. Both the conditional BXM and conditional PUT have higher returns than either the S&P Total Return Index or the respective unconditional option-selling strategies.

---

[5] Thus, each month, as we move forward in time from January 1995 onward, we have one additional month's data on VIX to compute its historical median.

18

Importantly, the conditional strategies offer meaningful improvements in both Sharpe and Sortino ratios over the market and over unconditional option selling in every period.

Exhibit 7 shows a comparison of the returns of the conditional strategies to the SPTR on an annual basis. The first column shows the annual returns of the SPTR, the second column the conditional Buy-Write strategy and the third column the conditional Put-Write strategy. This exhibit highlights the three different regimes for the strategy: years in which the strategy stays in the S&P, years where the strategy shifts to option writing and outperforms the S&P and years in which the strategy shifts to option writing and underperforms the S&P.
Exhibit 7
Annualized Return of S&P and the Conditional Write Strategies

Year	S&P Total Return	Conditional Buy-Write	Conditional Put-Write	Option Writing Months
1995	31.90%	31.90%	31.90%	0
1996	20.67%	18.07%	18.40%	10
1997	28.79%	23.62%	24.44%	12
1998	25.14%	17.35%	17.01%	12
1999	19.10%	19.20%	19.07%	12
2000	-9.55%	7.14%	12.28%	12
2001	-12.65%	-11.57%	-11.24%	12
2002	-24.98%	-7.95%	-8.97%	12
2003	25.22%	21.68%	22.93%	7
2004	10.33%	10.33%	10.33%	0
2005	4.80%	4.80%	4.80%	0
2006	14.66%	14.66%	14.66%	0
2007	5.35%	8.78%	9.64%	4
2008	-46.20%	-33.76%	-31.15%	12
2009	23.48%	23.04%	27.39%	12
2010	14.03%	5.51%	10.41%	10
2011	2.09%	6.90%	5.74%	6
2012	14.84%	8.88%	9.12%	4
2013	28.06%	28.06%	28.06%	0
2014	12.83%	12.83%	12.83%	0
2015	1.37%	-5.39%	-5.23%	2
2016	11.30%	8.47%	8.38%	2
2017	19.75%	19.75%	19.75%	0
2018	2.61%	4.73%	5.07%	3
Average	9.49%	10.09%	10.88%	

Denotes the strategies remained invested in S&P

Denotes the strategies outperformed S&P

The shaded rows show the years in which the strategies remain invested in the S&P all year long.

Out of the 23.5 years in Exhibit 7 there are seven years where this occurs (approximately 1/3 of

the time). These years directly correspond with positive S&P returns and low volatility environments.

The boxed areas show the years in which the strategies outperformed the S&P. Again, there are seven years where this occurred. These years generally coincide with periods of negative (or low) returns and higher volatility. On average the outperformance during these seven years is approximately 9.7%. This more than compensates for the nine years in which the strategies underperform as the average annual underperformance in those years is approximately 3.8%. These years of underperformance generally correspond with bull runs where the option premiums are insufficient to offset the capped upside of option selling.

Exhibit 8 shows the cumulative returns of the two conditional strategies and of the market.

Exhibit 8: S&P 500 and the Conditional Write Strategies
**January 1995 - June 2018**

Exhibit 8 highlights the performance of the strategies over time. After an initial period of underperformance, both strategies consistently outperform the S&P after its first sustained decline and then continue to outperform over the remainder of the period.

Exhibit 9 provides further insight into how the conditional strategies perform in market downturns. Based on monthly returns from 1995 through 2018 there were five periods in which the S&P dropped by more than 5% below its prior peak. The exhibit shows those periods and the associated drawdowns for the S&P as well as the conditional strategies. In all cases, the conditional strategies have smaller losses than the S&P alone. In fact, during the two longer drawdown periods in 2000 and 2007, the conditional strategies peak later than the S&P resulting in a drawdown that is not only shallower in severity but also shorter in duration. These smaller losses in down markets largely explain the higher risk-adjusted returns of the conditional strategies.

Exhibit 9
Performance of S&P and Conditional Write Strategies During >5% Drawdowns

| S&P Peak | S&P Trough | Drawdown Duration | | | S&P Total Return | Conditional Buy-Write | Conditional Put-Write |
		S&P 500	BXM	PUT			
Jun-98	Aug-98	2	2	2	-23.93%	-14.50%	-12.95%

Robustness of the Conditional Strategies

In the analysis above, we focused on Buy-Write and Put-Write indices compared with the S&P over the time period January 1995 through June 2018. We now consider the robustness of these strategies in two ways: (1) how the conditional BXM and PUT strategies perform over randomly selected periods of time, and (2) whether other variations of the BXM strategies can benefit from conditional deployment.

While the conditional strategies clearly outperform the S&P from 1995 through June of 2018, the annual performance presented earlier in Exhibit 7 also shows that in approximately one third of the years the conditional strategies underperform the S&P. This raises the question of whether the observed outperformance is simply an artifact of the particular time period we have analyzed. To examine this question, we utilize a Monte Carlo analysis in which we evaluate the performance of the conditional strategies over different time periods. We undertake this analysis by selecting 10,000 different periods with random start dates and random lengths of at least 12 months. Exhibit 10 below shows the results of these 10,000 different random periods. In this exhibit, we compare the percent of random time periods when the conditional strategies outperform the market and the unconditional variant of the respective option selling strategy.

Exhibit 10: Monte Carlo Analysis of Conditional Strategies

| | **Conditional Strategy Outperforms:** | |
	SPTR	**BXM (unconditional)**
Conditional BXM:		
Annual Return	82.9%	94.6%
Sharpe	92.4%	87.5%
Sortino	91.5%	88.5%
	SPTR	**PUT (unconditional)**
Conditional PUT:		
Annual Return	86.7%	93.4%
Sharpe	93.5%	75.6%
Sortino	92.2%	83.7%

As Exhibit 10 shows, the conditional strategies have greater returns over 90% of the time compared with either the S&P or the unconditional option writing strategies. The strategies also perform better in terms of downside risk as shown by better Sortino ratios in more than 70% of the outcomes. The Monte Carlo results provide compelling evidence on the robustness of our finding regarding the superior performance of the conditional option selling strategies.

Throughout this paper, we have focused our analyses on the BXM and PUT indices. As noted earlier, numerous academic researchers have documented variations of the buy-write strategy with the goal of improving returns such as writing 2% out of the money calls. The Cboe provides historical data for four variations of the BXM including:

a) BXY – 2% out of the money calls

b) BXMD – sells call option with delta closest to 30.

c) BXMC – sells ½ unit if VIX below 20, 1 unit if VIX above 20.

24

d) BXMW – utilizing weekly options over the next four weeks.[6]

Exhibit 11 shows the results of implement the conditional strategy on each of these covered call variations. In each case we find a similar outcome – the conditional strategy improves both the absolute and risk-adjusted performance when compared with the underlying index or the S&P alone.

Exhibit 11: Performance of Buy-Write Variations
January 1995 - June 2018

	Average Return	Standard Deviation	Sharpe Ratio	Sortino Ratio
SPTR	9.49%	14.63%	0.49	0.71
BXY (unconditional)	9.17%	12.33%	0.56	0.79
Conditional BXY	10.45%	12.79%	0.64	0.92
BXMD (unconditional)	9.45%	12.70%	0.56	0.81
Conditional BXMD	10.71%	13.27%	0.63	0.92
BXMC (unconditional)	9.05%	11.24%	0.60	0.84
Conditional BXMC	10.29%	11.87%	0.67	0.96

FURTHER RESEARCH

We have focused on option selling strategies in this paper based on a straightforward VIX-based rule. There are three main areas for further research. First, as highlighted in Exhibit 7, the strategy can underperform during long bull runs with elevated volatility such as that which occurred in the late 1990's. This suggests that the strategy might be improved by the consideration of other market

---

[6] Cboe only provides data for this index back to July 2012 due to availability of weekly S&P 500 options. While this index is not included in Exhibit 11 due to the limited data period available, over the period July 2012 to June 2018, the conditional strategy does improve absolute and risk-adjusted performance similar to the other indices.

25

conditions beyond volatility alone. The second main area concerns variations on the plain vanilla covered call strategy. In Exhibit 11 we saw that several variations of plain vanilla call writing also benefit from a conditional writing strategy. That said, as noted earlier, there is a vast literature which looks at a wide range of methods to improve the covered call strategy and one might wish to consider whether these variations might also benefit from a conditional strategy based upon market conditions.

One final area for further research is to examine whether the strategies might yield attractive returns when applied to more volatile emerging markets. Utilizing daily data on the ETF EEM to represent emerging markets and SPY to represent the US equity markets, we find that emerging markets are considerably more volatile than US equity markets. For example, over the past 15 years emerging market volatility was nearly 10 points higher than the volatility in US markets. This difference grows during periods of market turmoil, exceeding 22 points in 2008. This suggests that one might be able to generate even higher returns by using a conditional buy-write strategy in emerging markets.[7]

CONCLUDING COMMENTS

In this paper, we examined how buy-write and put-write strategies can be improved though a simple conditional strategy which sells options only when the VIX index is elevated. We started with an examination of market volatility. Consistent with prior studies, we found that implied volatility is consistently higher than future volatility. We extended this research by showing that

---

[7] The authors are aware of at least one fund (managed by a firm named WaveFront) which has actually implemented an emerging market buy-write strategy. That fund has found that their actual returns from implementing this strategy, even after accounting for transaction costs and other implementation charges, have often exceeded returns of the emerging market ETF and yielded superior Sharpe and Sortino ratios.

26

this overestimation grows at higher levels of the VIX index. After observing that this extends to option writing indices which exhibit excess returns during periods of elevated VIX, we developed conditional option writing strategies which only write options when the VIX is elevated above its historical median.

We document that these conditional strategies outperform both the S&P 500 Total Return Index and the continuous option writing strategies. Monte Carlo analysis shows that our results are robust across various time periods. These findings suggest that portfolio managers who are utilizing option writing strategies should consider selectively deploying this strategy only in market conditions that are characterized by higher than normal level of volatility.
